Utilization pattern of oral hypoglycemic agents for diabetes mellitus type 2 patients attending out-patient department at tertiary care centre in Bhopal, Madhya Pradesh, India

Jambu Jain¹, Parag Sharma¹, Jigisha Jain²*, Mustafa Raja¹

INTRODUCTION

Diabetes mellitus type 2 is a chronic disease that may be due to insulin deficiency and insulin resistance or both. The resultant hyperglycemia leading to micro and macro vascular complications and altered metabolism of lipids, carbohydrates, protein as well as an increased risk of vascular disease.¹⁻⁶ Type 2 diabetes is much more common and accounts for around 90% of all diabetes cases worldwide. It occurs most frequently in adults but incidence is increasing in adolescents as well.⁵,⁷ In 2015 the number of people with diabetes in the world was 415 million, as per International Diabetes Federation (IDF), which is going to increase to almost 642 million by 2040. India is emerging as a country with a large number of people suffering from diabetes. According to IDF, 69.1 million of adults in India suffered from diabetes in the year 2015.⁸ It has been predicted that the prevalence of diabetes in the adult population in India will be 6% by the year 2025.⁹

Modern principles of management of diabetes focus on disease prevention, screening of high risk individuals and aggressive treatment of individuals in the pre-diabetic state. The current pharmacotherapy of diabetes mellitus includes treatment with drugs such as insulin and oral hypoglycaemic agents. Various oral hypoglycaemic agents differ in their modes of action, safety profiles and...
tolerability. Main drugs differ in the mechanism of action as sulfonylureas and rapidly acting secretagogues stimulate insulin secretion, biguanides reduce hepatic glucose production, α-glucosidase inhibitors delay digestion and absorption of intestinal carbohydrate, thiazolidinediones improve insulin action and incretin based therapies like dipeptidyl peptidase-4 inhibitors boosts postprandial insulin release and lowers mealtime as well as fasting blood glucose in type 2 diabetics.\textsuperscript{10-12}

According to World Health Organization, drug utilization is defined as the marketing, distribution, prescription and use of drugs in a society with special emphasis on the resulting medical, social and economic consequences.\textsuperscript{13}

This kind of research in diabetes mellitus (DM) will provide useful insights into the different therapeutic traditions, reflect disease prevalence and data can be linked to adopt measures for decreasing morbidity and also to explore efficacy and toxicity of different therapies.\textsuperscript{14,16}

Therefore, drug utilization studies, which evaluate and analyze drug therapy are more meaningful, and observe the prescribing attitude of physicians with the aim to treat patient in a rational manner. Keeping all these facts in consideration, the present study was designed to analyze the prescribing patterns of oral hypoglycaemic drugs at L.N. Medical College and associated JK hospital, Bhopal, India.

METHODS

It was a prospective, observational and non-comparative study conducted at Medicine OPD in L.N. Medical College Bhopal, India. The present study was carried out in 200 established type 2 diabetes patients, who visited the hospital for treatment during the time period of January 2016 to April 2016. The study protocol was approved by institutional ethics committee.

**Inclusion criteria**

Type 2 diabetes mellitus patients, irrespective of age and sex, who were prescribed at least one oral hypoglycaemic drug (OHD).

**Exclusion criteria**

Diagnosed diabetic patients who do not receive pharmacological therapy, unable to reply verbal questions as well as mentally retarded and unconscious patients; patients with any malignancy; pregnant and lactating females.

**RESULTS**

A total of 200 diabetic patients were evaluated during the study period. Out of these patients 102 were male and 98 were female.

Majority of our patients were in the age group of 51-60 years (40%), followed by 62 (31%), 28 (14%) in the age group 61-70 and 41-50 respectively. Familial association with type 2 diabetes was seen in 36 (18%) of the patients. Male patients (n = 20, 55.6%) have shown more family history of diabetes mellitus than female patients (n=16, 44.4%).

During the study period, a total of 443 OHDs were prescribed to the patients. The average number of OHDs prescribed per prescription were found to be 2.2. Biguanides (n=170, 38.3%) were the most commonly prescribed class, followed by sulphonylureas (n=158, 35.6%), thiazolidinediones (n=88, 19.8%) and alpha-glucosidase inhibitors (n=27, 6%).

Among individual medicines, metformin (n = 170, 38.3%) was the most frequently prescribed OHDs, followed by gliclazide (n = 97, 21.89%) followed by pioglitazone (n=88, 19.8%), and gliclazide (n=51, 11.5%) (Table 3).

A significant number of patients were prescribed combination therapy (n=143, 71.5%) as compared to monotherapy (n=57, 28.5%), p <0.0001. Fixed dose combination (n=257, 58.01%) were more preferred over individual medicine (n=187, 42.2%) which was extremely significant (p <0.0001). The patients were treated with one (n=57, 28.5%), two (n=74, 37%), three (n=51, 25.5%), four (n=16, 8%) and five (n=2, 1%) OHDs.

Drug duplication was observed in five prescriptions (two in 5 drug regimen and three in 4 drug regimen). Almost all the medicines (n=435, 98.1%) were prescribed by brand name, only a fraction by generic name (n=8, 1.8%). Upward dose change was observed in 13 (6.5%).

A very high percentage (58.5%) of diabetes patients were found to be comorbid (p < 0.0001, extremely significant) with different types of diseases that included hypertension, (31%), followed by myocardial infarction, ischemic heart disease and hypothyroidism (3.5% each).
6.9 and 56.8 years respectively. Reported improved glycemic control was in the range: 18

either male or female preponderance was seen (males 51%, females 49%) (Table 1). Similar results were obtained in other studies conducted in Kerala and Ahmedabad in which the mean age of patients was 57.6 years (age range: 18-79 years) which is similar to that obtained in studies conducted in Nepal and Ahmedabad in which the mean age of patients was 56.9 and 56.8 years respectively.19,22

Majority of our patients were in the age group of 51-60 years (40%) which is in concordance with the earlier published literature.17,19,21,24 The mean age of the patients in the present study was 57.6 years (age range: 18-79 years) which is similar to that obtained in studies conducted in Nepal and Ahmedabad in which the mean age of patients was 56.9 and 56.8 years respectively.19,22

In the present study, neither male nor female preponderance was seen (males 51%, females 49%) (Table 1). Similar results were obtained in other studies conducted in India and other countries which have reported either male or female preponderance.19,23

However, a study from Tenali, Andhra Pradesh reported the mean age of patients as 53.4 years.31

The mean number of OHDs per prescription was found to be 2.2, which is higher than the number reported by Sutharson et al, and lower than the previous records of 2.99 from Hong Kong.25 In the present study metformin (biguanide) consumption was high (38.3%), followed by sulfonylureas (35.6%). Das et al, reported biguanides (24.5%) and sulphonylureas (19.9%) as the most commonly prescribed OHDs.26 Desai et al, reported the proportion of newly diagnosed patients initially treated with metformin increased from 51% to 65%, whereas those receiving sulfonylureas decreased from 26% to 18%.27 Bocuzzi et al, reported consumption of sulphonylureas that of 66.4% and metformin 24.3%.14 A study from Taiwan reported sulfonylureas as the most commonly prescribed drug class followed by biguanides.28

Metformin is the therapy of choice for overweight and obese patients with type 2 diabetes.29 Metformin acts as a peripheral sensitiser of insulin and also has beneficial effects on insulin resistance, an important factor in the pathogenesis of type 2 diabetes. It reduces cardiovascular-related mortality rates more than sulfonylurea.30 Metformin is unlikely to cause severe hypoglycemia, because it does not stimulate insulin release. So the physicians may have preferred metformin over other OHDs.

A large number of patients (71.5%) were prescribed combination therapy to control diabetes. Type 2 diabetes mellitus is a progressive metabolic disease which is difficult to control, so the physicians may have prescribed more combination medicines to control the blood glucose level in the type 2 diabetes patients. But to be on the cautious note, it may create problems in forms of drug duplication, chances of drug interaction and adverse drug reactions. A study reported improved glycemic control following the addition of sulfonylurca to metformin, but deterioration resumes as early as 6 months.31

It is recommended that only WHO approved fixed dose combination products should be prescribed. The use of hospital formulary as approved by a competent pharmacy

**DISCUSSION**

In the present study, neither male nor female preponderance was seen (males 51%, females 49%) (Table 1). Similar results were obtained in other studies conducted in Kerala and Ahmedabad.17,18 However, the results are in contrast to a few studies conducted in India and other countries which have reported either male or female preponderance.19,23
and therapeutic committee is also recommended for rational use of medicines. Furthermore lifestyle modifications, inclusive of dietary modification, regular physical activity and weight reduction are indicated for prevention of type 2 diabetes.\textsuperscript{32}

Change of dose and frequency was found to be an uncommon practice. Upward dosage change was observed in 6.5\% of the study patients, which is remarkably less than the findings of Bocuzzi et al who reported 15\% - 30\% upward dosage changes.\textsuperscript{14}

Inclination to brand name prescribing (98.1\%) was extremely significant (p <0.0001) in comparison to prescribing by generic names (1.8\%). In a recent Indian study from Allahabad, it was reported that only 2\% of the medicines were prescribed by generic names.\textsuperscript{33} Upadhyay et al., reported 47.5\% medicines prescribed by generic name in Nepal.\textsuperscript{19}

This might be due to the absence of hospital formulary system and biased promotion of selected brands by the medical representatives of pharmaceutical manufacturers, which is a common practice in Indian hospitals. Prescribing by generic names should be promoted, as it could help in cheaper treatment to the patients which will reduce chance of drug duplication, drug interactions and adverse drug reactions as well as result in better compliance because treatment of diabetes is lifelong.

More than half of the study population was found to be co-morbid with various conditions. Hypertension was found to be most commonly associated disease (34\%) with diabetes, which is well corroborated with the findings of Bener et al who reported 29\% hypertension as co-morbid in case of diabetics.\textsuperscript{34} These findings are significantly alarming, as hypertension is a predictor of cardiovascular disease.

CONCLUSION

Metformin was the most commonly used drug. The prescribing trend also appears to be moving towards combination therapy particularly two drug therapy. This study will contribute significantly to literature on drug utilization research. However, the study has its own limitations since follow-up of the patients was not possible and hence the effectiveness and tolerability profile of the anti-diabetic agents could not be assessed.

In the future one can investigate rationality of prescriptions, whether hospital formulary is followed or not as well as whether adherence to evidence based recommendations is seen or not.
