A prospective observational study to evaluate potential drug-drug interactions in patients admitted in intensive care unit, at BRIMS tertiary care hospital in Bidar, India

Shailander Singh, Swetha K.*

ABSTRACT

Background: Drug interaction occurs when presence of one drug affects the activity of another when, both are co-administered. 6-30% of adverse events (AEs) with significant hospitalizations or death are by drug-drug interactions (DDI). There is increased possibility to prevent the potential drug-drug interactions (pDDIs), if their prevalence and pattern are determined accurately before their occurrence. Hence this study aimed to evaluate the prevalence of pDDIs in ICU patients at BRIMS tertiary care hospital, Bidar.

Methods: This prospective observational study included 30 patients admitted in ICU of BRIMS hospital for >24hrs of either gender, aged >18yrs. The study was conducted for a period of 3 months. Data was collected from the case records of patients on the predesigned proforma. Potential drug-drug interactions were classified based on their severity and the risk of Potential drug-drug interactions was estimated by Lexicomp, inc.version; 3.0.1.drug interact android mobile application.

Results: Out of 35 patients admitted in the ICU, 30 cases were included in the study. The mean age of study population was 56.3years. The study population was exposed to a total of 330 medicines during the hospital stay with an average of 11.7 drugs per patient. The prevalence of pDDI was 93.3% (28) with an average of 9.75 pDDI per patient. According to Lexicomp drug interact android mobile application majority (63%) of pDDI were found to be moderate in their severity, 67% belonged to type C risk.

Conclusions: The study showed higher prevalence of pDDI among ICU patients due to the complexity of the pharmacotherapies administered.

INTRODUCTION

Drugs have beneficial therapeutic effects but they can also produce undesirable consequences. Drug-drug interactions (DDIs) are one such undesirable or a beneficial consequence of using two or more drugs simultaneously. DDI is a specific type of adverse event (AE) that occurs when there is an alteration in the effectiveness or toxicity of one drug due to presence of simultaneously administered another drug. This interaction leads to reduced, null or increased drug response.1,2 In most of the health care systems errors in practice are quiet common and these are reported to be the seventh most common cause of death overall.3 Evidence from epidemiologic studies shows that 6-30% of AEs with significant hospitalizations or death are caused by DDIs.4

Based on the mechanism by which drugs interact with each other, DDI can be classified as pharmacokinetic and pharmacodynamic. Risk factors for drug interactions can be related to patient, drug and medical prescription. Patient-related factors include people who are more vulnerable to drug interactions like the elderly with polytherapy, patients with hepatic or renal insufficiency,
patients with more than one prescribing doctor, those receiving intensive care (ICU), and immunosuppressed patients.\textsuperscript{3,7} Polytherapy increases the risk of clinically relevant drug interactions.\textsuperscript{6,7}

The development of drug-drug interactions is particularly common in ICU patients and this predisposition is complicated by disease severity and organ failure, both of which can change the pharmacologic response of medications.\textsuperscript{3,8} In ICU patient’s pDDI go unnoticed, as the symptoms due to DDI are masked by their preexisting disease symptoms. DDI has become a significant challenge to health care providers and may affect morbidity, mortality and patient’s quality of life.\textsuperscript{10}

Hence it is crucial to monitor these patients closely and the health care professionals should be trained efficiently in this aspect.\textsuperscript{11} There is increased possibility to prevent the potential drug-drug interactions (pDDIs), if the prevalence and pattern of pDDI are determined accurately before their occurrence.\textsuperscript{12} Unfortunately, there are limited studies on the preventability of adverse events (AEs) due to pDDIs. Hence this present study was aimed to evaluate the prevalence of potential DDIs in the ICU patients admitted at BRIMS tertiary care hospital, Bidar.

METHODS

A prospective observational study was conducted to assess the prevalence of pDDIs and to determine drugs involved in potential DDIs in the ICU patients admitted at BRIMS tertiary care hospital, Bidar, India. The study was conducted for a period of 3 months after obtaining Institutional Ethics Committee approval. Patients were selected randomly who were aged 18 years or older admitted to the Intensive Care Unit from October 2016 to December 2016, who had a length of stay of >24 hrs and had more than two medicines in their treatment chart were included in the study. Data was collected from the case records of patients on the predefined proforma, which included the following details:

- Demographic data.
- Provisional diagnosis.
- Prescription details: Number of drugs prescribed, drug class / category, dose, route, frequency and duration of administration.
- Length of stay in the hospital.

Potential drug-drug interactions were classified according to pharmacodynamics and pharmacokinetics properties and their severity and the risk of Potential drug-drug interactions will be estimated by Lexicomp, inc. version:3.0.1. drug interact android mobile application Table 1 and Table 2.\textsuperscript{3}

The data was analysed for pDDI by using drug interaction software Lexi-Comp, inc. version: 3.0.1.

The drug interactions that are not available in Lexi Comp Drug Interact were excluded from the study.

The diagnosis of the study patients was classified according to International Classification of Disease (ICD-10) and drugs were classified according to Anatomical Therapeutic Chemical classification system (ATC).\textsuperscript{10,11}

### Statistical analysis

Results are expressed as percentage for age, gender, diagnosis, length of ICU stay, number of drugs prescribed, severity and risk involved.

### RESULTS

A total of 35 patients were admitted in the ICU during the study period. Out of which 30 patients fulfilled the inclusion criteria and were included in the present study. Among the study population, 60% (18) were males and 40% (12) were females (Figure 1). In the present study, the mean age of the population was 56.3 years (Figure 2). Average length of hospital stay was found to be 6.4 days.

The study population was exposed to a total of 330 medicines during the hospital stay with an average of 11.7
drugs per patient. The major route of drug administration was parenteral that is, 61.5% (216) patients received parenteral medications while the rest 38.5% (135) patients received the drugs by other routes (Table 3).

A total of 93.3% (28) of patients were exposed to atleast one potential drug-drug interactions. The total number of potential DDI observed in the study period was 273, with an average of 9.75 potential DDI occurring per patient. According to Lexicomp drug interact android mobile application majority (63%) of potential DDI were found to be moderate in their severity (Table 4).

![Table 4: pDDI based on severity.](image3)

**DISCUSSION**

The present study assessed the prevalence of potential DDI in the ICU patients. 93.3% was the prevalence of pDDI in this study which is similar to a study conducted in the Northern India where the prevalence was 90.02% in MICU patients. Our study had male preponderance (60%) which was similar to a study conducted by Manjeeta Gupta et al.
Majority of the drugs were administered by parenteral route (61.5%) which is similar to a study conducted by Lima et al (62.3%). This is because most of the ICU patients are severely ill and require immediate drug effects.

</tbody>
</table>

One of the major things to be considered while monitoring the pDDI is its severity. This study showed 63% of the observed pDDI were moderate in their severity. A study conducted by Sainul Abideen et al in 72 MICU patients found that 64.15% of DDI were moderate in their severity. A study by Manjeeta Gupta et al showed a similar result, about 60% of the observed pDDI were of moderate in nature.

According to the Lexicomp drug interact risk scale of pDDI, in this study, category C was the most common 67% which required monitoring of therapy, followed by Category B (17%), D (14%) and X (2%). A study by Manjeeta Gupta et al reported a similar result, about 60.26% of pDDI belonged to category C while 14.41% and 3.93% belonged to category D and X respectively.

Our study showed that occurrence of pDDI was directly proportional to the number of drugs administered. This is in accordance with the study conducted by Reis et al which concluded that there is association between pDDI and the number of drugs used. Another study by Abideen et al also reported a similar finding that there is a positive relation between number of drugs used and chances of interaction.

This study showed similar results as compared to various other studies, that drugs in the cardiovascular system were the major category found to be interacting followed by alimentary tract and metabolism drugs.

The study was mainly based on the information obtained from the Lexicomp drug interact Application. The patients were not monitored for the occurrence of DDI clinically and also the significant relationship of co-morbidities and length of stay in ICU was not evaluated. Sample size was too small and limited study duration without any intervention were other limitations of our study.

ACKNOWLEDGEMENTS

Authors would like to express their gratitude and thanks to Dr. Gajanan P Kulkarni, MD Pharmacology Associate professor and in-charge Head of Department of Pharmacology, Bidar Institute of Medical Sciences, Bidar for permitting us to undertake this research work.
