ABSTRACT

Background: Diabetes mellitus is the fifth leading cause of death worldwide and is one of the common co-morbid conditions associated with coronary artery disease (CAD). The overall prevalence of CAD is 7.4% but the prevalence of CAD in diabetics is 9%. Hence treatment of hyperglycemia is a key goal of secondary preventive therapy with a target of reducing HbA1c to <7%. The risk of CAD has been reported to occur 2 to 3 decades prior in diabetics compared to non-diabetics. Hence discovery of drugs with potential role in both diabetes and CAD seems to be necessary. Ranolazine is a novel oral anti anginal drug known to reduce HbA1c and fasting blood glucose levels in angina patients with diabetes. The objective of this study is to show the effect of ranolazine (antianginal drug) on HbA1c and fasting blood glucose levels in diabetic patients with chronic angina.

Methods: Patients were divided into: Group 1 continued with previous antidiabetic drugs and antianginal drugs. Group 2 were prescribed Tab ranolazine 1000mg b.d (orally) as add on therapy along with previous antidiabetic drugs and antianginal drugs.

Results: There was a significant reduction in HbA1c and FBS levels in Group 2 patients who were on ranolazine. Reduction of HbA1c in group1 and Group 2 was 0.21±0.65% and 1.30±1.16% respectively. Reduction of FBS in group1 and group2 was 10.66±27.80mg/dl and 29.97±31.49mg/dl respectively.

Conclusions: From the present study we can conclude that ranolazine, an antianginal drug when given at a dose of 1000mg bd in diabetic patients with chronic angina reduces HbA1c and FBS levels.

INTRODUCTION

Diabetes poses a major health problem globally and is one of the top five leading causes of death in most developed countries.

A substantial body of evidence suggests that it could reach epidemic proportions particularly in developing and newly industrialized countries. Coronary artery disease (CAD) is one of the common co-morbid conditions associated with diabetes.1 Diabetes is an established risk factor for cardiovascular disease and risk increases with worsening hyperglycemia.2

Prevalence of CAD risk factors among diabetics is 63% and non-diabetics is 51%.3 The overall prevalence of CAD is 7.4% but the prevalence of CAD in diabetics is 9%.4,5

Risk of CAD was reduced by 20% in patients with a mean HbA1c of 6.5% compared to those with a mean level of 7.5%. Hence treatment of hyperglycemia is a key goal of secondary preventive therapy with a target of reducing...
HbA1c to <7%. The risk of CAD has been reported to occur 2 to 3 decades prior in diabetics compared to non-diabetics. Hence discovery of drugs with potential role in both diabetes and CAD is necessary. Ranolazine is a novel hemodynamically neutral antiangial and anti ischemic compound with cardioprotective properties and can be used both as monotherapy and as add on therapy when symptoms are not relieved with other antianginal drugs.

It was approved by FDA as an antiangial drug in 2006, but post hoc analyses of various angina trials suggested the drug might be effective in diabetic patients, not only for its role in eliminating angina but also for its ability to lower HbA1c levels.

Previous studies have shown that ranolazine 1000mg b.d in patients with diabetes and chronic angina can reduce HbA1c and FBS levels.

The aim of this study is to show the effect of ranolazine (anti anginal drug) on HbA1c and blood glucose levels when given in diabetic patients with chronic angina at a dose of 1000mg b.d (orally) for a period of 12 weeks in Indian population. Objective of this study is to evaluate the effect of ranolazine on HbA1c and FBS levels in patients of diabetes mellitus with chronic angina.

**METHODS**

This was open labelled prospective study. This study was conducted in the Department of Pharmacology, JJM Medical College, Davangere. This clinical study was conducted in patients suffering from diabetes with chronic angina, attending cardiology department, Bapuji hospital, Davangere. This study was conducted for period of 18 months.

**Inclusion criteria**

- Either gender, aged ≥18 years,
- Patients with chronic angina of ≥3 months,
- Patients with diabetes mellitus (HbA1c level >7% and FBS >140 mg/dl).

**Exclusion criteria**

- Renal failure,
- Chronic lung disease,
- H/o valvular heart disease,
- Hepatic failure,
- Patient on CYP3A4 inducers or CYP3A4 inhibitors
- Patients on drugs known to prolong QT interval e.g. quinidine, procaainamide, chlorpromazine etc.
- Pregnancy or absence of contraceptive use in women of child bearing age/ lactating mother.

A minimum of 62 patients fulfilling the inclusion criteria and who have given written consent were selected and divided into two groups:

**Group 1:** Patients in this group continued with previous antidiabetic drugs (sulfonylureas, metformin, insulin etc.) and antianginal drugs without ranolazine.

**Group 2:** Patients with inadequate control of angina symptoms were prescribed ranolazine 1000mg b.d as add on therapy along with current antidiabetic drugs (metformin, sulfonylureas, insulin etc.) and antianginal drugs.

All patients followed diabetic diet as recommended by physician. The following baseline parameters were recorded and repeated after 3 months. The parameters are:

- HbA1c (glycated hemoglobin),
- FBS.

Demographic details were also collected. Qualitative data was represented in the form of frequency and percentage. Association of variables was done with Chi Square Test and Fisher’s exact test for 2 x 2 tables where P value of chi square test was not valid due to small counts.

Quantitative data was represented in the form of mean and standard deviation. Comparison of mean within the group was done using paired t test. Mean difference between the two groups was done using unpaired t test and by Mann-Whitney U test if the data fails Normality test. Statistical analysis done using IBM SPSS Version 20 for Windows.

**RESULTS**

All the baseline parameters were comparable in both the groups except for frequency of angina (Table 1).

In group 1 patients, there is a reduction of HbA1c levels from baseline to after 3 months with a p-value of 0.09 which is statistically not significant. There is also a reduction of FBS from baseline to after 3 months with a p-value <0.04 which is statistically significant (Table 2 and Figure 1).

In group 2 patients, there is a reduction of HbA1c levels from baseline to after 3 months with a p-value of p<0.001 which is statistically highly significant. There is an also reduction of FBS from baseline to after 3 months with a p-value <0.001 which is statistically highly significant (Table 3 and Figure 2).

When intergoup comparison is done for mean reduction in HbA1c between group 1 and group 2, the results are statistically highly significant with p-value <0.001 showing that ranolazine has HbA1c reducing property. When intergoup comparison is done for mean reduction in FBS between group 1 and group 2, the results are statistically significant with p-value = 0.010 (Table 4 and Figure 3, Figure 4).

DISCUSSION

CAD and DM are two distinct disease entities which are interlinked. Metabolic derangements in diabetes leads to increased risk for CAD.

Ranolazine is a novel oral anti anginal drug known to reduce HbA1c and fasting blood glucose levels in angina patients with diabetes.12 The present open labelled prospective study was conducted to assess the effect of ranolazine on HbA1c and fasting blood sugar levels in patients of diabetes mellitus with chronic angina.

The baseline characteristics and concomitant medications were similar in both the groups, hence comparable which is similar to the study conducted by Selvarajan S et al where ranolazine is compared with trimetazidine to evaluate for the reduction in HbA1c levels.12 Patients in group 2 had increased frequency of angina per week compared to group 1. Ranolazine is indicated in patients with chronic angina who are inadequately controlled with first line antianginal drugs as an add on therapy therefore patients in group 2 received ranolazine as an add on drug (Table 1).

The type of antidiabetic drugs used for group 1 and group 2 patients with a history of diabetes was similar. The majority of patients were taking either metformin and/or sulfonylurea which is similar to the study conducted by Selvarajan S et al.12 There were no major changes in the antidiabetic drugs in both the groups between 0 and 3 months. Hence, the effect of ranolazine on FBS and HbA1c does not appear to be attributable to use of concurrent anti diabetic therapy in ranolazine-treated patients group 2 (Table 1). Both the groups have received similar antianginal and other drugs (Table 1).
In group 1, the mean reduction of HbA1c in group 1 from baseline to 12 weeks was 0.21\% which is not statistically significant with p value of 0.09 (Table 2 and Figure 1). This is similar to the study conducted by Timmis A et al where change in HbA1c levels from baseline to 12 weeks was 0.02\% which was also not statistically significant.\textsuperscript{11} However there was a statistically significant reduction of FBS with a p-value <0.04 (Table 2 and Figure 1).

In Group 2, the mean reduction in HbA1c level from baseline to 12 weeks was 1.3±0.46 which is statistically highly significant with a p-value <0.001 (Table 3 and Figure 2) Results from our study is similar to the results from the study conducted by Timmis A et al where change in HbA1c levels from baseline to 12 weeks was 0.70±0.18\% which is also statistically significant and also in a study by Chisholm JW et al ranolazine reduced HbA1c by 1.2\% in 12 weeks.\textsuperscript{11,10}

Similarly reduction in group 2 FBS from baseline to 12 weeks was 29.97±20.81mg/dl which is statistically highly significant with a p-value <0.001 (Table 3 and Figure 2). Same results are also reflected in a study conducted by Chisholm JW et al to evaluate the effect of ranolazine on HbA1c and blood glucose levels, where reduction in FBS was 25.7mg/dl.\textsuperscript{10}

When comparison is done for reduction in HbA1c, the mean difference in the reduction of HbA1c between group 2 and group 1 was found to be 1.09±0.5. The results are statistically highly significant with p-value <0.001 showing HbA1c reducing property of ranolazine.

The mean difference in the reduction in FBS between group 2 and group 1 was 19.31±3.69 which is also statistically significant with p-value = 0.010 (Table 4, Figure 3 and Figure 4).

Similarly, results are seen in 2 studies conducted by Timmis A et al and Chisholm JW et al, where ranolazine was found to effective in reducing HbA1c and blood glucose levels when compared to placebo.\textsuperscript{11,10}

It was observed that the HbA1c lowering property of ranolazine was greater in patients with more marked hyperglycemia i.e. with HbA1c levels of >9%.

Though the magnitude of reduction of HbA1c levels by ranolazine appears small, it is important to note that this additional beneficial effect is from the drug which is already established to be an antianginal drug. No adverse effects were reported by patients taking ranolazine. Previous studies have shown that ranolazine 1000mg b.d in patients with diabetes and chronic angina can reduce HbA1c and FBS levels.

CARISA study done by Adam D Timmis, Bernard, Michael, dept of cardiology, London showed that Ranolazine significantly lowered HbA1c by 0.70±0.18\% in patients with diabetes mellitus and chronic angina when given at a dose of 1000mg b.d for 12 weeks. The results of this study suggested that ranolazine may be an effective and well tolerated antianginal medication in diabetic patients with chronic angina.\textsuperscript{11}

MERLIN-TIMI-36 study done by Jeffrey, Allison, Arvindu, Eugen demonstrated the effects of ranolazine on HbA1c and glucose levels using prespecified glycemic end points followed at an interval of 4.8 and 16 months. This study showed that ranolazine 1000mg twice daily reduced HbA1c by 1.2\% and FBS by 25.7mg/dl.\textsuperscript{10} In our study there was a reduction of HbA1c by 1.3\% and FBS by 29.97 mg/dl in ranolazine treated patients.

A study done by Selvarajam S, showed that ranolazine when given at 500mg b.d for 12 weeks had no effect on HbA1c and FBS levels.\textsuperscript{12} Hence it was decided to use 1000mg b.d in our study.

The mechanism of action (MOA) by which ranolazine reduces HbA1c levels is unclear. Ranolazine as an antianginal drug acts by inhibiting a late Na\textsuperscript{+} current (late I\textsubscript{Na}) in the myocardium which indirectly facilitates Ca\textsuperscript{2+} entry through Na\textsuperscript{+}/Ca\textsuperscript{2+} exchanger. Reduction in Ca\textsuperscript{2+} overload in the myocardium during ischemia decreases contractility and has a cardioprotective effect.\textsuperscript{13} Pancreatic α cells also express voltage gated Na\textsuperscript{+} channels which support the generation of electrical activity and cause an increase in intracellular calcium, leading to exocytosis of glucagon. Ranolazine may exerts its antidiabetic effects by inhibiting glucagon release via blockade of Na\textsuperscript{+} channels in the pancreatic α-cells. This MOA is unique in that no other approved antidiabetic drugs acts via this mechanism.\textsuperscript{14} Further studies are required to elucidate the exact mechanism of action.

Diverse nature of background anti diabetic medications is one of the limitations of the study, other being short duration of study. Hence ranolazine may be an effective and well-tolerated anti-anginal medication in diabetic patients with chronic angina since it has an additional antidiabetic action. However, further studies on larger population for longer duration are needed.
